Role of Glutamine in Protection of Intestinal Epithelial Tight Junctions

RadhaKrishna Rao and Geetha Samak
Department of Physiology, University of Tennessee Health Science Center, Memphis, TN

Introduction

In addition to its important role in digestion, absorption and secretion, the gastrointestinal epithelium serves as a barrier to the diffusion of toxins, allergens and pathogens from the luminal contents into the interstitial tissue. Barrier disruption and diffusion of noxious substances are known to induce mucosal inflammation and tissue injury. In fact, the disruption of gut barrier function plays a crucial role in the pathogenesis of numerous gastrointestinal diseases such as inflammatory bowel disease (IBD), irritable bowel syndrome (IBS), celiac disease and infectious enterocolitis. The specialized junctional complexes called tight junctions provide the intestinal epithelial barrier function. Loss of tight junction integrity and increased intestinal permeability to macromolecules are associated with the pathogenesis of IBD, IBS and celiac disease. Mucosal protective factors such as growth factors and nutrients preserve the gut barrier integrity and are beneficial in the treatment of various gastrointestinal diseases. L-Glutamine the most abundant amino acid in blood plays a vital role in the maintenance of mucosal integrity. Glutamine is traditionally termed as a nonessential amino acid, is now considered a “conditionally essential” amino acid. Its consumption in small bowel mucosa exceeds the rate of production during catabolic stress such as trauma, sepsis and post surgery [1, 2]. In the small bowel mucosa, glutamine is an unique nutrient providing fuel for metabolism, regulating cell proliferation, repair and maintaining the gut barrier functions [3]. The focus of this article is on the role of L-glutamine in the preservation of gut barrier function and the epithelial tight junction integrity and gut barrier function.

L-glutamine, the most abundant amino acid in the biological fluids

L-Glutamine is an amide of glutamic acid with amine as the functional group. It is the most abundant amino acid in both intracellular and extracellular compartments produced by the action of glutamine synthase as it is required for number of cellular functions. The intracellular concentration of L-glutamine range from 2 mM to 20 mM [2], where as its concentration in extracellular fluid and plasma is about 0.7 mM (4, 5). The plasma concentration of L-glutamine is significantly reduced under the conditions of extraneous exercise (2, 6, 7) and under severe shock and trauma (8, 9). Although adequate glutamine is produced in the body to maintain the normal physiological functions in the cell, the
depletion of glutamine under conditions of exercise and stress makes the body depend on exogenous glutamine to supplement the body glutamine pool to meet the requirement. Therefore, L-glutamine is a conditionally essential amino acid (1).

L-Glutamine has multiple physiological functions

Glutamine plays multiple roles in the maintenance of physiological homeostasis of diverse organs and cell types. It is best known for its ability to serve as a source of fuel for the cells such as enterocytes, renal epithelial cells, hepatocytes, neurons, immune cells, β-cells of pancreas (3). Glutamine metabolism plays multiple roles in nitrogen balance, regulation of glucose metabolism and acid base homeostasis. It is quantitatively the most important donor of ammonia in kidney and liver, and plays a role in maintaining the acid-base balance of body fluids. Alkalosis with elevated ammonia level is associated with increased production of glutamine, while during acidosis glutamine is broken down to glutamate and ammonia serving to elevate plasma pH (10–12). It is a major transporter of nitrogen from the sites of synthesis (skeletal muscle, liver and lung) to the sites of utilization (kidney, intestine, neuron and immune cells) and serves as a nontoxic ammonia shuttle in the body (13, 14).

Glutamine is utilized at a high rate in rapidly dividing immune cells and promotes many functional activities of immune cells such as T-cell proliferation, B-cell differentiation, phagocytosis, antigen presentation, cytokine production and neutrophil superoxide production (15, 16). Muscle tissue is a major site of glutamine synthesis where it forms the anabolic precursor for muscle growth. Glutamine is essential for the growth, survival and physiological health of actively dividing cells such as enterocytes, fibroblasts and lymphocytes (17). It is also an important osmolyte for cell volume control and shown to increase hepatocyte cell volume by eliciting anabolic process (6, 18, 19).

L-Glutamine is the precursor for synthesis of few peptides, amino sugars, purines, pyrimidines, nucleic acids and other nitrogenous compounds in the cells. The synthesis of glutathione, a major endogenous antioxidant in mammalian cells, requires glutamine as a precursor. Glutathione protects most cells from oxidative injury. Several metabolic products derived from glutamine also include neurotransmitter, proline and hexosamines (20). Glutamine/glutamate is a substrate involved in the ureagenesis in liver and gluconeogenesis in liver and kidney.

Pathophysiology of glutamine deficiency

Glutamine is a non-essential amino acid under normal physiological conditions, as it is produced in the body in adequate amounts. However, under conditions of severe infections, physical trauma, radiation-induced damage and major burns the physiological level of glutamine is inadequate and therefore required to be supplemented with dietary glutamine. Normal range of plasma glutamine level is 500–750µmol/L. Prolonged exhaustive exercise leads to nearly 25% drop in plasma glutamine level. Plasma glutamine level falls also during fasting and in patients with untreated diabetes mellitus. In all these cases catabolic stress occurs by rise in plasma cortisol and glucagon by enhancing the physiological demand for glutamine for gluconeogenesis. Heavy physical training leads to reduction in plasma glutamine level below 500 µmol/L. The recovery of such deficit requires a long period,
which is the causing factor in the development of overtraining syndrome among athletes (2, 7). Certain pathological conditions leading to catabolic stress where intracellular glutamine levels may drop below 50% and plasma concentration below 30%, body requirement for glutamine overwhelms the capacity of body for de novo synthesis of glutamine (21), and therefore depends on dietary glutamine supplementation. Sepsis and other severe illnesses leading to multiple organ dysfunction results from nitric oxide and peroxynitrite generation leading to oxidant injury in a glutamine-deficient environment. Similar type of local tissue injury is seen in ischemia and reperfusion (22, 23). Therefore, depletion of tissue glutamine can be viewed as a compromised body defense system, which is a likely mechanism in the pathogenesis of various clinical conditions.

Glutamine is essential also for the growth and viability of cell lines in culture, and requires that it is present in the medium 10–100 fold in excess of other amino acids. Presence of glutamine in the medium cannot be substituted with glutamic acid or glucose (2, 24). Glutamine deficiency leads to cell death in many human cell lines. Enteral administration of glutamine stimulates intestinal mucosal protein synthesis and protects enterocytes from apoptosis. Animal and clinical studies have shown that glutamine deprivation leads to villous atrophy, mucosal ulcerations and cell necrosis in the small intestine (25). There is an increased susceptibility to infections due to decrease in plasma glutamine concentration which impairs the functioning of immune cells (26).

Gastrointestinal mucosal protection by glutamine

Gastrointestinal mucosa is lined with multifunctional, rapidly proliferating epithelial cells. They form a primary interface between luminal contents and the interstitial tissue. These cells are dependent on both luminal and systemic sources for their nutrition and are affected by intra and extra-luminal nutrient intake. During the normal life time 60 tons of food pass through gastrointestinal tract posing continuous threat to the integrity of gastrointestinal tract and whole body. Hence this organ is often under the challenge of inflammatory diseases and cancer (27). Under normal physiological conditions, proteases, dietary components, drugs, microbes and other factors usually cause minor damage to mucosa. Gastrointestinal mucosal integrity is quickly restored and maintained by cell proliferation, migration, restitution and differentiation. A host of growth factors and regulatory peptides play protective and healing roles to meet this challenge. Furthermore, the salivary secretions, gastrointestinal mucosal secretions and factors of intra-luminal microflora jointly preserve the normal homeostasis (28, 29). The enteral feeding appears to be the primary stimulus for the regulation of proliferative response in the intestinal tract, which is accomplished mainly by the L-glutamine. Gut mucosa is the major site of Glutamine metabolism. It is an important anoplerotic substrate in the mucosal cells and forms important source of energy accounting to about 35% of the total carbon dioxide produced from various substrates in the intestinal mucosa. Glutamine also mediates several other protective influences on the gastrointestinal tract and forms an important dietary component to maintain gut mucosal integrity (30–32).

Gastrointestinal tract plays a central role in catabolic response after injury and infection. Prolonged stress and trauma leads to a drop in body glutamine pool causing mucosal atrophy. Oral Glutamine supplementation supports gastrointestinal mucosal growth and
prevents the mucosal and villous atrophy in patients receiving total parenteral nutrition (TPN) (33, 34). Animals when supplemented with glutamine during TPN also showed a dose-dependent increase in mucosal weight. Glutamine facilitates enteral absorption of nutrients and electrolytes in animals with experimental diarrhea (35). It also lessens the severity of diarrhea by enhancing water and salt intake. It protects the gut epithelium from ammonia-induced cell death (36–39).

Glutamine prevents the gastrointestinal injury induced by radiation, which is of importance under the conditions of radiation therapy in cancer patients. Radiation and chemotherapy causes bowel injury and reduced mucosal lymphocyte count (40, 41). Administration glutamine-rich diet protects the gut mucosa from injury and ulceration caused by radiation. L-glutamine supplementation raises the level of mucosal and plasma glutathione (GSH). Enteral glutamine also stimulates mucosal protein synthesis during sepsis and attenuates ubiquitin-dependent proteolysis and improves the protein balance of gut. Mechanism of oral glutamine supplementation-induced gut mucosal protection against starvation, stress, trauma, radiation and other pathological conditions involves increase in the rate of protein synthesis and decrease in proteolysis (42, 43).

Glutamine is a major source of energy for proliferation and differentiation of intestinal epithelial cells (44). Dietary supplementation of glutamine found to be beneficial in maintenance of normal intestinal villous morphology and average daily body weight gain in weaned piglets (45). Lack of glutamine attenuated the growth of two types of intestinal epithelial cells, IEC-6 and Caco-2 in culture in vitro, which was reversed by the addition of nucleosides suggesting the role of glutamine amide nitrogen pool for the synthesis of nucleotide and glucosamine in the intestinal mucosa (46). Glutamine is necessary for enterocyte proliferation, fluid and electrolyte absorption and mitogenic response to growth factors. It is required for maximal stimulation of intestinal epithelial cell proliferation by EGF (47, 48). EGF activates Glutamine transport activity across the intestinal epithelial membrane through protein kinase C (PKC) and MAP kinase (MAPK)-mediated cell signaling (49). Due to its multiple roles in the gastrointestinal tract glutamine demand in the gastrointestinal mucosa is more than 15g/day, which is obtained mainly from systemic circulation as there is very little glutamine synthase activity in the gastrointestinal mucosa. Hence gastrointestinal mucosa derives glutamine formed in other tissue and also from diet for its metabolism (50). The evidence available to support the beneficial effect in maintenance of gastrointestinal mucosal homeostasis is summarized in Table 1.

**Gut permeability and glutamine**

Gastrointestinal mucosal epithelium provides a structural and immunological barrier against the broad spectrum of noxious and immunogenic substances present the lumen of the gut. Compromised intestinal mucosal integrity and breakdown of gastrointestinal mucosal barrier function, a condition generically referred to as “Leaky Gut Syndrome”, are associated with starvation, injury, infection, immunosuppression, chemotherapy, and lack of enteral feedings, radiation and other types of stress. Disruption of gut mucosal integrity and barrier dysfunction results in increased permeability to allergens, toxins and pathogens, leading to immunological stress response and inflammation (28, 34). Severe trauma and burn increases
intestinal permeability to bacteria and endotoxins leading to sepsis and multiple organ failure (51). A rapid rescaling of gut epithelial barrier function following injury under physiological conditions is essential as infection is a major cause of morbidity.

A significant body of evidence indicates that glutamine preserves the gut barrier function and prevents permeability to toxins and pathogens under various conditions of gastrointestinal mucosal injury. Glutamine is considered the most important nutrient for healing of ‘leaky gut syndrome’ because it is the preferred fuel for enterocytes and colonocytes (52). Low level of serum Glutamine concentration correlated with intestinal barrier disruption, inflammation and diarrheal diseases among children (53, 54). Glutamine supplementation causes a profound improvement in intestinal barrier function in highly stressed patients and patients in TPN. Glutamine-fortified parenteral and enteral diets significantly improve the intestinal morphology and function (32, 55, 56). Factors triggering the increase in intestinal mucosal permeability during trauma and illness include oxidative stress, proinflammatory cytokines, hypoxia and reduction in intramucosal pH. Clinical and animal studies have demonstrated that the administration of glutamine before or immediately after surgery reduced the intensity of increase in intestinal permeability and systemic inflammatory response (57). Glutamine-induced recovery in intestinal barrier function by reducing bacterial translocation was demonstrated in laboratory animals (58). It stabilizes intestinal permeability and reduces pancreatic infection in acute experimental pancreatitis (59).

Several animal studies demonstrated that experimentally-induced hyper permeability can be alleviated by the addition of glutamine or glutamine peptide leading to improved gut barrier function as well as immune function in the gut (56). Gut barrier dysfunction and endotoxemia are associated with the pathogenesis of inflammatory bowel diseases, such as ulcerative colitis and Crohn’s disease. Glutamine supplementation significantly reduced clinical and endoscopic scores in patients with ulcerative colitis (60). Therefore, both experimental studies and clinical observations indicate that glutamine plays a crucial role in maintenance and restoration of gut barrier function.

**Regulation of epithelial tight junctions by glutamine**

The epithelial tight junctions constitute the major component of gut barrier function, which acts as physical and functional barrier against the paracellular penetration of macromolecules from the lumen (61). Therefore, disruption of tight junctions is an initial event associated with the pathogenesis of many gastrointestinal diseases. The tight junction is organized by four types of transmembrane proteins, occludin, claudins, tricellulin and junctional adhesion molecules, which interact with the scaffold proteins such as ZO-1, ZO-2 and ZO-3 (62, 63). ZO-1 anchors the transmembrane proteins of tight junctions to the actin cytoskeleton and interacts with other tight junction proteins. Tight junction proteins interact with numerous signaling proteins that regulate tight junction assembly and maintenance, indicating the potential role of intracellular signaling pathways in the regulation of epithelial tight junctions and barrier function (64).
Stress, food allergies, alcohol, antibiotics, malnutrition are some of the factors that lead to leaky gut syndrome. Leaky gut or increased intestinal epithelial permeability has been implicated in the pathogenesis of several gastrointestinal diseases such as food allergies, IBD and IBS (65, 66). Glutamine is likely a potential intervention strategy for these diseases, as it reduces intestinal permeability from various stressors and helps maintain the normal intestinal barrier function (41, 59, 67). Deprivation of dietary glutamine in infant rats by inhibiting glutamine synthase resulted in increase of bacterial translocation (68). Inflammation during chronic fatigue syndrome is a result of increased gut permeability and bacterial translocation. Glutamine in combination with N-acetyl cysteine and zinc partially restores the tight junction integrity and attenuated gut-derived inflammation (69). Ischemia-reperfusion increases gut permeability by disrupting the epithelial tight junctions. Enteral glutamine restored the small bowel barrier function after ischemia/reperfusion injury in rats by elevating the level of intestinal GSH (70–72). Glutamine supplementation was found to be beneficial in decreasing intestinal permeability induced by non-steroidal anti-inflammatory drug (73). Intestinal permeability and bacterial translocation in an animal model of experimental biliary obstruction was attenuated by glutamine administration (74).

TPN is associated with increased jejunal permeability and glutamine supplementation prevented this effect and reduced the TPN-induced jejunal atrophy. Glutamine supplementation is of critical importance as it is related to energy supply to proliferating and differentiating enterocytes (75). Administration of glutamine in burn-injury patients resulted in an increase in plasma glutamine concentration from 0.44 mM to 0.61 mM, significantly reduced the intestinal permeability to lactulose/mannitol, and accelerated wound healing (51). Glutamine administration improves the prognosis of critically ill patients by maintaining intestinal barrier and by reducing the frequency of infections (57).

The importance of glutamine in preserving the intestinal epithelial barrier function is further supported by several in vitro studies using the cell culture models of intestinal epithelium. Glutamine deprivation or inhibition of glutamine synthase in Caco-2 cells in culture significantly decreased the transepithelial electrical resistance (TER) and increased the paracellular permeability of the cell monolayer (52) and increased bacterial translocation (66). Glutamine deprivation reduced the expression of tight junction proteins, claudin-1 and occludin and induced redistribution of these protein from the intercellular junctions (76). Our studies demonstrated that acetaldehyde, the carcinogenic metabolite of ethanol, disrupts the intestinal epithelial tight junctions. L-Glutamine prevents the acetaldehyde-induced increase in permeability to endotoxin by preventing the disruption of tight junction and adherence junction in Caco-2 cell monolayer (77). The glutaminase inhibitor, 6-diazo-5-oxo-L-norleucine, failed to affect the glutamine-mediated protection of barrier function, indicating that this protective effect of glutamine did not require metabolism of glutamine, and that intact glutamine is involved in this protective function. Glutamine attenuated the acetaldehyde-induced redistribution of occludin, ZO-1, E-cadherin and β-catenin from the intercellular junctions. Similarly, pretreatment with L-glutamine significantly attenuated acetaldehyde-induced redistribution of occludin, ZO-1, E-cadherin and β-catenin from the intercellular junctions in human colonic mucosa (78).
Role of EGFR in the mechanism of glutamine-mediated tight junction regulation

The molecular mechanisms regulating the effects of glutamine on intestinal barrier function is poorly understood. The lack of an effect of glutaminase inhibitor on glutamine-mediated protection of barrier function indicated that the intact glutamine is responsible for the protective function. The delineation of signaling pathways involved in glutamine mediated-protection of intestinal barrier function may include many routes vowing to its multi-faceted beneficial effects. Our study on the effect of L-glutamine on acetaldehyde-induced disruption of tight junction and increase in paracellular permeability clearly demonstrated that L-glutamine prevents acetaldehyde-induced disruption of the tight junction and increase in the permeability in Caco-2 cell monolayer by an EGF receptor-dependent mechanism (77, 78).

EGF is a peptide growth factor of 53 amino acids. EGF is secreted in saliva and other gastrointestinal secretions at high concentrations (79). EGF is an important gastrointestinal mucosal protective factor that protects the gastrointestinal mucosa from various insults (79, 80). Our studies indicated that EGF prevents acetaldehyde-induced disruption of tight junction and adherens junctions and reduce the paracellular permeability in Caco-2 cell monolayer by a phospholipase Cγ, protein kinase C (PKC) and MAP kinase (MAPK)-dependent mechanisms (81–83). The protection of tight junction and adherens junctions from acetaldehyde by L-glutamine was also mediated by PKC and MAPK-dependent mechanism (77). The protective effect of L-glutamine on acetaldehyde-induced permeability is mediated by a transactivation of EGF-receptor tyrosine kinase activity. A selective inhibitor of EGF receptor tyrosine kinase, AG1478 significantly attenuated the glutamine-mediated prevention of acetaldehyde-induced reduction of the levels of tight junction and adherens junction proteins in detergent-insoluble fraction of Caco-2 cell monolayer and human colonic mucosa (77, 78). L-Glutamine induces a rapid tyrosine phosphorylation of EGF receptor (77, 78). These studies indicated that L-glutamine protects tight junction barrier function by turning on PKC and MAPK-mediated cell signaling via transactivation of EGF receptor. The mechanism associated with EGF receptor transactivation by glutamine is unclear. However, our preliminary study (unpublished) indicates that extracellular ligand-binding domain is required for this EGF receptor transactivation. Therefore, we speculate that L-glutamine induces release of EGF receptor ligands into the extracellular medium. The signaling mechanisms associated with L-glutamine-mediated protection of intestinal epithelial tight junctions is summarized in figure 1.

Furthermore, a recent study demonstrated that glutamine deprivation alters intestinal tight junctions via a PI3K/Akt-mediated pathway in Caco-2 cells. Deprivation of Glutamine increased phospho-Akt protein, while glutamine supplementation enhanced the barrier function of Caco-2 monolayer (84, 85).

Summary and perspective

L-Glutamine is the most abundant and conditionally essential amino acid due to body’s inability to synthesize in adequate amounts during stressful conditions like trauma and...
sepsis. It is an oxidative fuel for enterocytes, lymphocytes and plays an important role in maintaining homeostasis with respect to nitrogen balance, acid-base balance and glucose metabolism. Number of clinical and experimental studies demonstrated its importance as a dietary supplement in maintaining gastrointestinal mucosal barrier function and in preventing bacterial and endotoxin translocation during parenteral nutrition, sepsis, infection, radiation and other various catabolic stress conditions. Hence Glutamine is an essential nutrient for gut mucosal epithelial cell growth, differentiation, mucosal integrity and barrier function. Several cell culture studies further confirm its role in the regulation of mucosal epithelial tight junction integrity. L-Glutamine protects tight junctions in Caco-2 cell monolayers and human colonic mucosa from acetaldehyde-induced permeability change and redistribution of tight junction and adherens junction proteins from the intercellular junctions. This protective effect of L-glutamine appears to be mediated by the transactivation of EGF receptor leading to activation of PKC and MAPK.

There is ample evidence to indicate that L-glutamine is the essential dietary supplement to help maintain mucosal integrity and barrier function under physiologic and pathophysiologic conditions. Human gut has little capacity to synthesize Glutamine and therefore it relies on the glutamine supply by other tissues and diet. Over the last decades of clinical trials of glutamine supplementation in critical illness, surgical stress and cancer have shown significant benefit by reducing the rate of mortality, length of hospital stay and infectious morbidity. Parenteral glutamine administration (>0.25–0.3g/kg/day) demonstrated the greatest benefit in hospitalized patients (86). Glutamine-based oral rehydration therapy (ORT) was found to be as effective as glucose-based ORT for rehydration, however with additional benefit with regard to repair of intestinal barrier in patients with diarrhea (53).

Therefore, a growing body of evidence advocates the use of L-glutamine in the clinical practice. Further understanding and application of glutamine-based therapeutics can be enhanced by future studies geared toward our understanding of the molecular mechanisms associated with glutamine-mediated protection of gastrointestinal epithelial tight junctions and the mucosal barrier function.

L-Glutamine supplementation induces transactivation of EGF receptor EGFR) potentially by excreting metalloproteinases (MMP), which in turn releases membrane bound TGFα and potentially other EGFR ligands leading to EGFR activation. EGFR activation leads to stabilization of actomyosin and tight junctions by a mechanism that involves activation of PLCγ, PKCβI and PKCε. Glutamine deprivation on the other hand leads to activation of PI3K and Akt.
